Response to reviews on “Compensation between meridional flow components of the AMOC at 26°N”

E. Frajka-Williams et al.

March 7, 2016

We thank the editor and reviewers for their time and attention to our manuscript. Reviewer 1 highlighted the strengths of the manuscript, identifying it as “an exciting and clearly written paper on the RAPID data,” for which we offer our thanks. Reviewer 2 raised some concerns that the paper might be written a little too much for a RAPID-centric audience, so we have added some additional details in both the methods and conclusions to help identify the main findings of the paper. Please find below our detailed responses to the reviews interspersed between the original comments of the reviewers. Our replies are in italics. We also include a revised draft of the manuscript with the changes highlighted.

1 Response to Reviewer 1

Major comment A: “The authors used definitions of the UNADW and LNADW based on depth rather than density. The depth-based definitions make it almost impossible to compare the transport estimates reported in this paper against the other transport estimates of UN-ADW and LNADW, which are almost always based on density, e.g. the estimates at the Line-W (Toole et al. 2011). I guess that the decision to use the depth-based definition may be due to lack of measurement for the density structure in the interior. However, the geostrophic transport of a density layer is technically only based on only the end points, same as the geostrophic transport of a depth-based layer. In addition, the isopycnal surfaces are mostly flat in the interior of the basin anyway. So I think the authors should at the very least provide the density-based transports along with the depth-based estimates to allow a comparison with the other studies.”

Unfortunately, translating from boundary-profiles of dynamic height to transports in density space (which require interior information) is not straightforward to do well as the relationship is not one-to-one. In the interior of the basin, the mooring array has quite coarse horizontal resolution, which makes translation into accurate density coordinates challenging. In particular, from hydrographic sections, the Labrador Sea Water layer spans the Mid-Atlantic Ridge, while the Denmark Strait Overflow Waters are concentrated in the western basin. While we agree that transport in density space is important, further study is required to determine whether transports in density space can be resolved well enough to compare to other latitudes. The reviewer mentions the transports at line W which uses a different array design (current meters to resolve the deep western boundary current, DWBC), but it is not obvious that the width of the DWBC captured there could be easily translated to a DWBC at 26°N. We believe that such an extensive analysis would be beyond the scope of the present paper.
Major comment B: “One of the most interesting findings in this study is that the strong compensation between the sub-annual variability of UMO and FC observed in the full 10-year record is absent in the first 3-years, as previously reported by Kanzow et al. (2010). However, the authors only briefly discuss about this apparent non-stationarity with the Figure 10. I think a further examination of this non-stationarity may provide some hints about the mechanism involved in the compensation. How unusual was the first 3-years statistically? Perhaps the authors could examine the 3-year running window correlation to quantify how unusual the first 3-years was. Furthermore, the authors suspected the eddies to be responsible for the compensation. If so, does an independent measurement of eddies in this region, e.g. EKE from the satellite altimeter, exhibit a reduced activity during the first 3-years? Please examine this interesting aspect a bit further.”

We have added additional discussion to the text, referring to the findings of an earlier GRL paper led by the lead-author here, titled “Eddy Impacts on the Florida Current”. In that paper, we showed that there was a strong correlation between the Antilles Current (east of the Bahamas) and the Florida Current (west of the Bahamas), during the period 2009-2011. Concurrently, the rms-anomaly of SSH east of the Bahamas (over the Antilles Current) was larger amplitude subsequent to 2009. A detailed study of the EKE, while interesting, would be beyond the scope of this paper - however that is an area for future research within the group.

New paragraph in manuscript: The compensation between the FC and UMO is non-stationary. A windowed correlation between the FC and UMO prior to 2007 shows no significant correlation, either between the full time series or the high-pass filtered time series (not shown). From Frajka-Williams et al. [2013], the FC and Antilles Current (AC) were correlated between 2009 and 2011. The AC is a narrow, northward boundary current east of the Bahamas. Its transport is measured by direct current meter measurements in the RAPID array, and is included in the UMO transport. The mean transport of the AC is relatively small (3.6 Sv, compared to 31 Sv in the FC), so that the UMO transport is still net southward. However, since the AC is part of the UMO transport, a correlation between the FC and AC should weaken an anti-correlation between the FC and UMO. The isopycnal displacements associated with UMO and FC variability (Fig. 7) also influence transport in the AC, as long as the AC is geostrophic. The mooring used to estimate isopycnal displacements is at the western edge of the UMO transport, but is east of the core of the northward AC velocities. This means that a downward displacement of isopycnals is associated with an increase in the tilt of the thermocline between Africa and the mooring, but will have an opposing effect on geostrophic transports west of the mooring, in the Antilles. Frajka-Williams et al. [2013] identify stronger eddy activity east of the Bahamas during the period of FC and AC correlation, which is consistent with a eddy activity playing a role in the anti-correlation between the FC and UMO on subannual timescales.

Major comment C: “Another aspect that may deserve a further investigation is the role of the wind stress curl forcing in the reported compensation, which may shed a light on the respective roles of the barotropic and baroclinic components in the observed compensation. The 0.5 - 1 day lag (Fig. 6e) may indicate a dominant role for the barotropic component. If so, does the wind stress curl averaged along the 26degN exhibit significant correlations with UMO, FC, and Ekman transports? Or does the power spectrum of the wind stress curl averaged along the 26degN exhibit a similar structure as the coherences shown in the Figs. 9-10? On the other hand, the concentration of the compensation near the western boundary may suggest a role for
either the baroclinic response to the local wind stress curl or the barotropic response along the
western boundary topo-graphic wave guide. These aspects could be investigated based on the
correlation of the transport components with the wind stress curl in different locations."

Indeed, we are presently investigating the role of wind-stress curl forcing on transports at
26°N. Given the short duration of the record, however, it has proven difficult to say with certainty
that the relationships we are finding, in spite of significant correlations. Over the 10-year record,
these transport time series have 2 peaks and 2 troughs, with similar timescales of variability as
that of the winds, so any conclusions must be considered cautiously, in terms of their statistical
significance. Again, we would argue that this is beyond the scope of the present paper.

Detail comments

1. Please add the horizontal and vertical grid lines in all the time series

Some grid lines have been added, but we find that too much clutter in a figure makes it
harder to see the data.

2. P.2711, L.8-11: Please quantitatively compare the first and last 5 years in terms of the
number of days with flow reversal.

There were 10 days in the latter 5 years (zero days in the early 5 years). Days with a
reversal included 19-24 Dec 2009 and 9-13 Mar 2013. Details have been added to the first
paragraph of section “Ten years of MOC and mid-ocean variability” (L141-43).

3. P.2711, L.15-17 and Table 1: Are the mean transports still statistically significantly different
if the two periods are divided as 2004-2010 and 2010-2014? This could be one way to assess
the robustness of the long-term transport reduction in the record.

2009 was an anomalous year with the lowest transport observed during the observations and
so separating the time series in 2010 instead of 2009 does change the results. However, it
is perhaps better to exclude this one year when looking at the long term trend as was done
in Smeed et al 2014 (tables 2 and 3 in that paper), which reduced the change/trend but
did not eliminate it. Here, separating into a 6-year and a 4-year mean as suggested by the
reviewer, the mean transports are statistically significantly different for all transports except
UMO. Separating the two periods in 2010 suggests that the UMO transport difference is
only significant at the 13% level.

4. Figure 4 caption: It seems the data plotted in the panels c-d are not de-trended, unlike the
panels a-b. However, this is unclear in the caption.

The data in panel c and d are low-pass filtered, while panels a and b are detrended. This
has been clarified in the caption.

5. Figure 4a and the related text: The UMO has the sum of three components, ie Twbw, Tint,
and Text (Eq.1). What are the correlations of each component against the FC?

The correlation between the FC and WBW, which is dominated by the Antilles Current, is
addressed in Frajka-Williams et al. [2013]. It is significantly and positively correlated over
the period after April 2009. The Text has the same time variability as the LNADW only,
and is not correlated with the FC. The remaining transport is the Tint, which is governed
by isopycnal displacements and is responsible for the observed signal. Due to the limited
physical significance of the individual components (see comment below), the text has not be
updated.

6. P.2716, L.9-20: The argument in this paragraph could be more straightforward if the
correlation of the Twbw, Tint, and Text against the Ekman transport is explicitly provided.
The separation of Tint and Text is somewhat arbitrary (due to the choice of the reference
level), and the Twbw is the Antilles Current but also includes some of the DWBC, so the
separations, while originating from the observations and methodology are not necessarily
useful physically.

We show below the time series separated (and related to the FC and Ekman), as suggested
by the reviewer. As it turns out, the FC is better correlated with the sum of Twbw, Tint
and Text than any individual component. It is about equally correlated with the Tint+Text
transport. Ekman transport is not correlated with either deep Twbw (which is mostly above
2000 m), or deep Tint (which is very small due to the lack of shear below 3000m). It is
correlated only with the external component of the MO transports.

7. P.2717, L.11: “(1500-bottom)” -> “(1500 m – bottom)”
Thank you, this has been corrected.

8. Figure 7b and the related text: As 3000 m is about the height of the Mid-Atlantic Ridge
(MAR), shouldn’t the MAR sub-arrays also be considered?
The MAR sub-arrays do not show the variability we’ve found in the transbasin transports, in
that isopycnal displacements from the MARwest and MAReast moorings are not correlated
with transport time series. This has been added to the text (as “not shown”).

9. Figure 8a and c: The colors for the curves indicated in the legends and the y-axes do
not match. For example, the y-axes for the depth are in black, while the curves for the
isopycnal displacement are not in black.
*Thank you, the legends and curves have been corrected.*

10. Figure 9 and P.2718, L.15-19: The coherences between FC and UMO as well as that for
LNADW and Ekman transport are not significant for the periods shorter than 60 days.
What is the explanation for this high frequency cut-off?
While the FC and UMO have no coherence below 50 days (and marginally significant
coherence from 50-70 days), the LNADW and Ekman do have some coherence below 50
days. Our focus in this study is primarily at longer time scales, which is why we binned
our data into a bi-monthly time scale. We plan future analyses that will focus more on the
shorter periods.

11. Figure 10 caption: Are the arrows shown only when the co-spectra are statistically
significant? Please clarify in the caption.
Thank you, this has been clarified.

12. Figure 11 caption: “Eq. (2)” -> “Eq. (3)”?
Thank you, this has been corrected.
Figure 1: Correlation between the FC and three components of the Mid-Ocean transport (a) $T_{wbw}$, (b) $T_{int}$, (c) $T_{ext}$, and (d) the sum, over the depth range 0-1100 m.
Figure 2: Correlation between the Ekman and three components of the Mid-Ocean transport (a) $T_{wbw}$, (b) $T_{int}$, (c) $T_{ext}$, and (d) the sum, over the depth range 3000-5000 m.
2 Response to Reviewer 2

To make more clear which results discussed in this paper are new as the reviewer suggested, we have added three sentences to the Conclusions:

- L455. In this paper, we have provided a brief overview of the latest 18-months of observations.
- L463. The main result of this paper has been detailing newly-identified compensations between MOC components (UMO and FC, and LNADW and Ekman).
- L481. Finally, investigating longer-term variations of the MOC, we can localize the origin of the intensifying trend in the MOC to isopycnal displacements on the western boundary.

Here we list our replies to the detailed comments the reviewer inserted into the highlighted manuscript they submitted as a supplemental addition to their review.

1. Seven years long -> Seven years length
   This has been changed.

2. “These low frequency changes have consequences for the heat content across the subtropical and tropical North Atlantic”. I don’t understand this. Is it a reference to heat flow across a line or heat content in an area?
   This sentence has been revised to read “These low frequency transport changes have been shown to be responsible for changes in ocean heat content in the subtropical and tropical North Atlantic.”

3. “Observed trend of -0.5 Sv” should be Sv/yr?
   Thank you, this has been updated.

4. P2708, L2: “The depth structure and time scales of these variations are explored, illustrating an important role for the western boundary below 1000 m.” Is it transport along the western boundary?
   This has been revised to read: “illustrating an important role for the western boundary below 1000 m in setting transport variability.”

5. P2708 L17. “The exact number of moorings and instruments has varied over the past decade and over 20 deployment and recovery cruises.” Verb?
   This has been changed to: The exact number of moorings and instruments has varied over the past decade during which there have been over 20 deployment and recovery cruises.

6. “near the surface to 500m at the bottom” –> Suggestions: close to the bottom.
   This has been updated

7. Pg 2708. Map of array?
   We have added a parenthetical note to suggest that readers see Figure 1.1 of McCarthy et al. (2015) for a detailed map of the array.
8. Pg 2709. The transport is a function of z. Barotropic is normally understood as depth independent. As far as I can see, McCarthy et al. 2015 does not claim that this term is barotropic.

Here, the velocities are barotropic (depth-independent), but due to the width of the basin, the transports are not barotropic. This has been clarified as “Due to changes in the width of the basin as a function of depth, though the applied flow is barotropic (depth-independent), the transport-per-unit-depth has decreasing magnitude with increasing depth.”

9. Pg. 2710. “It is a rather complicated filtering of data. Rationale? Reference? Details of filtering is given here, but in figure 1, a month low-pass filter has been applied. What about this filter?”

*We agree that the filtering applied sounds complicated. The text has been clarified to indicate that the first step of the filtering is applied during the standard RAPID processing (which corresponds to the publicly available dataset). From this starting point, we have applied additional filtering. We have tweaked the pertinent paragraph in the Methods section to make this more clear (L105-112).

The time series in Figure 1 are our starting point - the publicly available data set. We have included in the caption the basic processing information (i.e. filtering) done on that data set; our more detailed processing discussed in the Methods section applies to the remainder of the analysis in the paper.

10. L2710. “For the purpose of calculating isopycnal displacements, in this study, absolute salinities and conservative temperatures on the twice-monthly time grid are used. For reference pressures from the surface to bottom, a mean density profile is calculated within 400m of the reference pressure, and isopycnal displacements from the mean depth are calculated. Displacements are then mapped back onto the mean depth of each density surface using the time mean profile.” I don’t understand what is done with the data. Time mean? Lateral mean? Please rewrite.

These have been modified and clarified with additional detail in the text, L117-128.

11. L2713 & L2714. “sign (note that the negative of UMO is plotted in Fig. 4a),” I suggest to introduce this note at the of the second paragraph of this section. UMO plotted in both b.

This has been removed, with the plotting details noted in the caption.

12. Fig. 9 caption, purple -> green

This has been updated

Abstract

From ten years of observations of the Atlantic meridional overturning circulation at 26° N (MOC, 2004–2014), we revisit the question of flow compensation between components of the circulation. Contrasting with early results from the observations, transport variations of the Florida Current (FC) and upper mid-ocean transports (UMO, top 1000 m east of the Bahamas) are now found to compensate on sub-annual timescales. The observed compensation between the FC and UMO transports is associated with horizontal circulation and means that this part of the correlated variability does not project onto the MOC. A deep baroclinic response to wind-forcing (Ekman transport) is also found in the lower North Atlantic Deep Water (LNADW, 3000–5000 m) transport. The observed compensation between the FC and UMO transports is associated with horizontal circulation and means that their individual variability does not project onto the MOC. In contrast, covariability between Ekman and the LNADW transports does contribute to overturning. On longer timescales, the southward UMO transport has continued to strengthen, resulting in a continued decline of the MOC. Most of this interannual variability of the MOC can be traced to changes in isopycnal displacements on the western boundary, within the top 1000 m and below 2000 m. Substantial trends are observed in isopycnal displacements in the deep ocean, underscoring the importance of deep boundary measurements to capture the variability of the Atlantic MOC.

1 Introduction

The Atlantic meridional overturning circulation (MOC) is a key part of the global ocean circulation, redistributing heat and properties around the globe. The continuous daily time-series observations at 26° N are the first of their kind, capturing the transbasin circulation variability on timescales of days to – now – a decade.

From the first year of observations, Cunningham et al. (2007) noted considerable high-frequency variability of the MOC, with values ranging from 5–35 Sv. This exceeds the range
of all previous estimates of the MOC strength at 26° N derived from hydrographic sections (Bryden et al., 2005). After three years of data were recovered, a seasonal cycle of the MOC became apparent (Kanzow et al., 2010), with a maximum in July–November and a minimum in March, and a seasonal range of approximately ±3.5 Sv. This seasonal cycle has been captured by numerical simulations (Xu et al., 2014) and may be explained by variations in wind-forcing on seasonal timescales (Yang, 2015; Duchez et al., 2014). Kanzow et al. (2010) also noted that the components of the MOC (the Florida Current, the interior thermal-wind contribution and the Ekman flow) were largely uncorrelated, suggesting that each contributes variability to the MOC independently. Once the MOC records had stretched to seven years in length, striking interannual variability and more recently a declining trend in the MOC were revealed (McCarthy et al., 2012; Smeed et al., 2014). These low frequency changes have consequences for the heat content across transport changes have been shown to be responsible for changes in ocean heat content in the subtropical and tropical North Atlantic (Cunningham et al., 2014; Bryden et al., 2014).

Numerical investigations into the sources of variability to the AMOC Atlantic MOC interannual variability suggest that much of the variability may be attributable to winds (Roberts et al., 2013; Zhao and Johns, 2014; Yang, 2015) (Cabanes et al., 2008; Roberts et al., 2013; Zhao and Johns, 2014; Yang, 2015; Pillar et al., 2016). Buoyancy forcing instead affects decadal variations (Polo et al., 2014; Yeager, 2015). An estimate of the MOC from high latitude density anomalies suggests a decline of the MOC (Robson et al., 2014) which is presently observed at 26° N (observed trend of −0.5 Sv/yr, Smeed et al., 2014) though it may not be indicative of a longer-term decline (Roberts et al., 2014). The 26° N array provides an estimate of the MOC, but separating it into components and even depth ranges of anomalies may aid in the identification of physical causes of change (Wunsch and Heimbach, 2013).

In this paper, we introduce the 10 year record of the MOC at 26° N, describing features of the variability in the most recent 18 months and across the ten-year record, and examine more fully the degree of correlation or compensation between MOC components using the longer records. While much of the recent research into Atlantic MOC variability has focused on interannual timescales and longer, here we quantify newly observed compen-
sation between the Florida Current and UMO transports, and covariability between the deep transbasin transports and zonal winds, on sub-annual timescales. The depth structure and time scales of these variations are explored, illustrating an important role for the western boundary below 1000 m. Lower frequency changes in MOC components, including the continuing trend in the vertical shear of the mid-ocean transport, are also described. Finally, we conclude by discussing the origins of the lower-frequency variability in the 10 year records.

2 Methods

The international 26° N RAPID Climate Change/Meridional overturning circulation and heat flux array (hereafter RAPID 26° N) has provided comprehensive daily measurements of the MOC at 26° N for ten years so far (April 2004–March 2014; Smeed et al., 2015). The MOC is defined as the northward transport above the depth of maximum overturning (roughly 1100 m) across 26° N, and is constructed as the sum of three components: the surface meridional Ekman transport (Ek) estimated from reanalysis winds, the Gulf Stream transport through the Florida Straits – the Florida Current (FC) – measured by a submarine cable (e.g. Meinen et al., 2010), and the upper mid-ocean (UMO) transport, measured by a trans-basin array of current meter and dynamic height moorings between the Bahamas and Africa. The exact number of moorings and instruments has varied over the past decade and more than during which there have been over 20 deployment and recovery cruises. The main western boundary mooring which we used here is called WB2, and typically has 18 MicroCAT (Seabird Electronics, Bellevue, WA) conductivity–temperature–depth instruments. Vertical resolution ranges from 75 m near the surface to 500 m at near the bottom. Overall, the accuracy of the MOC transport is estimated to be 1.5 Sv (ten-day values) or 0.9 Sv (annual averages). Full details of the array configuration and map (their figure 1.1), transport calculation and associated errors can be found in McCarthy et al. (2015).

Here, we focus on the trans-basin or mid-ocean (MO) transport, from which the UMO is derived. The MO transport is constructed from three parts:

\[ \text{MO}(z) = T_{wbw}(z) + T_{int}(z) + T_{ext}(z), \]  

(1)
where $T_{wbw}$ is the western boundary transport estimated from direct current meter measurements, $T_{int}$ the “internal” transbasin transport and $T_{ext}$ the “external” flow. The western boundary wedge transport, $T_{wbw}$ includes most of the flow associated with the Antilles Current. The “internal” transport, $T_{int}$, is the baroclinic flow zonally-integrated across the remainder of the ocean interior relative to an assumed level of no motion at 4820 dbar. It is derived from dynamic height moorings near the western and eastern boundaries and over the Mid-Atlantic Ridge. Here we focus on the western and eastern profile contributions to the $T_{int}$. Using only the western and eastern density contributions to interior transport-per-unit depth, we have that $T_{int}(z)$ relative to the reference level ($z_{ref}$) is related to density as

$$T_{int}(z) = -\frac{g}{f\rho} \int_{z_{ref}}^{z} \left[ \rho_e(z') - \rho_w(z') \right] dz' ,$$

(2)

where $g$ is gravitational acceleration, $f$ the Coriolis parameter, and $\rho_e(z)$ and $\rho_w(z)$ the density profiles at the eastern and western boundary, respectively (Rayner et al., 2011).

The “external” flow, $T_{ext}$, is the (unmeasured) interior barotropic flow that ensures zero mass transport across the section. This component is calculated as a residual of the other components and is applied as a uniformly-distributed (small), and thus depth-independent, velocity across the entire mid-ocean section, which we refer to as “hypsometric compensation”. Due to changes in the width of the basin as a function of depth, even though the applied flow is barotropic, the transport-per-unit-depth has decreasing magnitude with increasing depth. Kanzow et al. (2007) showed that this estimate – derived from mass conservation – was in good agreement with an independent estimate of the mid-ocean barotropic flow derived from bottom pressure gauges deployed across the section over the April 2004–April 2005 period.

The MO transport can be further divided into its contributions to the upper and lower branches of the overturning circulation. The UMO is defined as the depth-integral of MO transport between the surface and the time-varying depth of maximum overturning. The mean depth of the maximum overturning is at approximately, roughly 1100, and in practice
there is not much difference between a UMO defined with a time-varying bottom limit of integration vs. a bottom limit fixed at 1100 m. The lower limb of the MOC is made up of southward flowing North Atlantic Deep Water, which is split into contributions associated with upper North Atlantic Deep Water (UNADW; 1100–3000 m) and lower North Atlantic Deep Water (LNADW; 3000–5000 m). The sum of these two transports recovers nearly all the variability of the MOC ($r = 0.996$, McCarthy et al. 2012). The small difference is equal to the flow between 1100 m and the depth of maximum overturning and a contribution from the hypsometric compensation below 4820 bar.

For the analysis presented here, we start with the RAPID data as processed for the publicly available dataset. This processing involves filtering individual instrument records were with a two-day low-pass filtered then subsampled onto 12-hourly intervals before computing transports, and filter to remove the tides, and subsampling onto 12-hourly intervals. From this subsampled dataset, transport components are computed, then further ten-day low-pass filtered with a 5th-order Butterworth filter. Time series were binned onto a 5th-order Butterworth filter before the compensation transport is calculated (Kanzow et al. 2007). These data are available from http://rapid.ac.uk. Here we additionally bin the data onto a twice-monthly time grid, then remove the twice-monthly climatology to reduce seasonal variations. For lower frequency variations, twice-monthly time series are deseasonalized and deseasonalized time series are further filtered with a 1.5 year Tukey filter. Significance and confidence intervals are reported at the 95% level, unless otherwise indicated. The number of degrees of freedom was calculated using the integral timescale of decorrelation to the first zero crossing (Emery and Thomson 2004). When a year is denoted 2009/10, it refers to the period 1 April 2009 through 31 March 2010.

For the purpose of calculating isopycnal displacements $\zeta$, in this study, absolute salinities and conservative temperatures on the twice-monthly time grid are used. Isopycnal (\(\sigma\)) displacements are then calculated following Desaubies and Gregg (1981), as

$$\zeta(\bar{z}(\sigma), t) = z(\sigma, t) - \bar{z}(\sigma),$$
using locally-referenced densities. For example, to determine the displacement of the
isopycnal typically found at 1000 dbar, potential densities are calculated referenced to
1000 dbar ($\sigma_1$). Using these locally-referenced densities, the mean density at 1000 dbar
is identified ($\sigma_i = \langle \sigma_1(z=1000,t) \rangle_t$). The depth of this density, $z(\sigma_i,t)$, is then determined
for each timestep in the locally-referenced densities, and differenced from its mean depth
(~991 m for 1000 dbar). This produces isopycnal displacements as a function of density,
which can then be mapped back onto depth using the mean relationship between depth and
density ($\bar{z}(\sigma_i)$). This process of locally-referencing densities is repeated for each pressure
surface from the surface to the bottom at 20 dbar intervals.

For reference pressures from the surface to bottom, a mean density profile is calculated
within 400 m of the reference pressure, and isopycnal displacements from the mean depth
are calculated. Displacements are then mapped back onto the mean depth of each density
surface using the time mean profile. The detrended and low-pass filtered time series are
processed as above. When a year is denoted 2009/10, it refers to the period 1 April 2009
through 31 March 2010.

3 Ten years of MOC and mid-ocean variability

All of the ten-year time series of transport components at 26° N show high frequency vari-
ability (Fig. 1a). In the most recent 18 months, additional features of the time series include
a large Ekman transport reversal in March 2013 (similar to the two reversals that occurred
in 2009/10 and 2010/11). During this March 2013 event, the Ekman transport anoma-
lies exceeded two standard deviations from the mean, with the typically northward-flowing
water turned to the south. This reversal was similar in magnitude to the December 2009–
March 2010 event, but with shorter duration (Fig. 1a). On several occasions, as during the
negative Ekman events in 2005, 2010 and 2013, the FC also showed sharp, short-term
reductions in transport. These corresponding anomalies led to sharp reductions – or even
brief reversals – of the MOC at these times. Over the past 10 years, the MOC was negative
from 19-24 December 2009, and from 9-13 March 2013. The Ekman transport reversals
also coincided with reductions of the southward LNADW flow (Fig. 1b). In the most recent 5 years, the LNADW experienced more short periods of reversal (i.e., a northward flow of the net transport below 3000 m) than had been observed in the first 5 years of the record. These high frequency events in the deep flow exhibit fairly weak vertical shear, with maximum anomalies below 3000 m (Fig. 2a).

The MOC exhibits substantial variability at time scales longer than annual (Fig. 3). Interannual variability of the MOC derives primarily from the UMO component, with a negative trend in both over the full 10 year record. The mean and standard deviation of the MOC for the first five years of observations is $18.4 \pm 1.3$ Sv and the second five years $15.5 \pm 1.9$ Sv (these values are significantly different, see Table 1). While some of this change is contributed by the 2009/10 dip (McCarthy et al., 2012), the intensification of the southward thermocline flow (UMO) has persisted with the associated weakening of the MOC. The 2012/13 year was the second weakest year of the MOC (14.2 Sv), behind the 2009/10 year (12.8 Sv). In contrast to the 2009/10 year, the weak MOC in 2012/13 had very little contribution from the wind-driven Ekman transport, but instead is associated with a strong southward thermocline flow (UMO).

Transport-per-unit depth anomaly profiles show the depth-structure of mid-ocean transport variations. In the top 1100 m, the southward UMO has intensified (Fig. 2b, shift from red to blue), while below 3000 m the southward LNADW has weakened (shift from blue to red). Previous analyses have shown that variability of the UMO on interannual timescales is primarily governed by changes at the western boundary (Frajka-Williams, 2015). The amplitude of these changes is larger in the top 1000 m, but anomalies below 1000 m span a large portion of the water column.

4 Correlation between transport components

During the first three years of observations (2004–2007), the components of the MOC (FC, UMO and Ekman) showed little covariability, leading to the conclusion that components contribute their variability independently to the MOC (Kanzow et al., 2010). More recently,
sporadic periods of covariability were identified between currents at the western boundary: the FC and Antilles Current from 2009 to 2011 (the end of the record at the time of publication) (Frajka-Williams et al., 2013). From the ten-year record (2004–2014), we now see correlations emerging between some of the contributing terms, which has implications for how we understand the large-scale circulation at 26° N. Considering the 3 month filtered UMO and FC transport time series (black lines in Fig. 1), anomalies of opposite sign appear to coincide in late 2008, late 2010 and again in late 2012. During the 2010/11 winter, for example, the northward flowing FC weakened by several Sverdrups. At the same time, the southward flowing UMO weakened by nearly 10 Sv. We investigate these apparent compensations (between the UMO and FC, and also between LNADW and wind-driven Ekman flow) more rigorously in the following section.

4.1 UMO and FC transports: Horizontal circulation

The FC carries most of the waters of the Gulf Stream across 26° N. The origins of this water come from the Yucatan Channel and Old Bahama Channel, across complex topography west of the Bahamas (Rousset and Beal, 2014). At similar latitudes, the flow through the Yucatan Channel has been found to compensate flow around Cuba (Lin et al., 2009), while variations in the FC have, at times, shown compensation east of the Bahamas in bottom pressure variations (Bryden et al., 2009) and in top 1000 m velocities (Frajka-Williams et al., 2013).

Here we consider compensation between FC and UMO, the transbasin transport east of the Bahamas. This compensation can be clearly seen by plotting their detrended anomaly time series (Fig. 4a). Certain events stand out, demonstrating almost perfect correspondence between the two time series, with examples including February–May 2007, September 2008–June 2009, August 2010–January 2011 and August 2012–March 2013 (highlighted in the figure). Notably, these episodes of correlation are absent in the first 3 years. The overall correlation between the two records is \( r = -0.49 \), significant at the 95% level.

Fluctuations in UMO compensate fluctuations in the FC by similar magnitudes (slope = \(-0.92\), Fig. 4b). When the northward FC transport increases along the western boundary,
the southward UMO transport east of the Bahamas intensifies by the same amount. This means that excess northward flow in the boundary current is returned horizontally within the upper mid-ocean circulation rather than by deeper layers in the interior, which would have involved changes in the MOC. The region east of the Bahamas is known to be rich with eddies which may influence the transbasin transports (Wunsch, 2008; Kanzow et al., 2009; Thomas and Zhai, 2013; Clément et al., 2014; Xu et al., 2014), and due to the timescale of observed compensation, we suspect that eddies are involved.

Using the low-pass filtered time series, this high degree of compensation is absent (Fig. 4c and d). Instead, strong interannual variability in the UMO remains (Fig. 4c). By comparison, the low-pass filtered FC shows little interannual variability, consistent with previous work that indicated that the interannual and longer period FC variability is of much smaller amplitude than the sub-annual variability (e.g. DiNezio et al., 2009; Meinen et al., 2010). While the two time series are not significantly correlated ($r = 0.24$), both show a reduction from the first five-year period (April 2004–March 2009) to the latter five-year period (April 2009–March 2014, see also Table 1), with the FC reducing by 0.7 Sv and the UMO by 1.9 Sv. Unlike the compensation at higher frequencies, these changes are both of the same sign (note that the negative of UMO is plotted in Fig. 4a), compounding the effect on the MOC (net reduction of 2.9 Sv).

### 4.2 LNADW and Ekman transports: Deep wind-driven response

Another – and perhaps more remarkable – correlation that emerges from this analysis is between the deepest limb of the southward mid-ocean transports (LNADW) and the surface meridional Ekman transport (Fig. 5a). Using the detrended anomaly time series, the typically southward LNADW transport can be seen to reduce or even temporarily reverse to northward during strong Ekman transport reversals. (See e.g., events in December 2009–April 2010, November 2010–January 2011, February–March 2013.) The correlation is statistically significant ($r = -0.58$), and can be seen to occur throughout much of the record rather than just during the extreme events. In the low-pass filtered data (Fig. 5c and d),
the correlation is stronger than for the UMO and FC. However, due to the low number of degrees of freedom for the low-pass filtered time series ($\text{ndof} = 5$), it is not significant.

As with the FC and UMO compensation, magnitudes of fluctuations between Ekman and LNADW match (slope $= -0.84$, with Ekman anomalies of 1 Sv corresponding to a 0.84 Sv change in the LNADW). Unlike for the FC and UMO, however, the correlation between the LNADW and Ekman at higher frequencies projects onto the MOC rather than cancelling. This is consistent with expectations that the high frequency, wind-driven variability of Ekman transport results in an overturning, albeit a shallow one (where the depth of overturning is at the base of the northward Ekman transport) between the surface Ekman transport and return flow below (Jayne and Marotzke, 2001; Killworth, 2008). Variations in Ekman or FC project directly on the mid-ocean transport (through the $T_{\text{ext}}$ term in 2), and bottom pressure records at the western boundary also covary with Ekman anomalies (McCarthy et al., 2012). However, we will show that the covariations between FC, Ekman and mid-ocean transports are not limited to the $T_{\text{ext}}$ contribution, but are instead associated with density changes at the western boundary.

To identify possible lags between the UMO and FC or Ekman and LNADW, we use the 10 day filtered time series. For both correlations, between the UMO and FC and between the Ekman and LNADW, the timescale of the response is fast (Fig. 6). For the LNADW and Ekman correlation, a maximum correlation of $r = 0.51$ is found at 1 day lag with Ekman leading. This means that the wind response occurs essentially instantaneously. For the UMO and FC transports, a maximum correlation of $r = 0.46$ is found for UMO leading by 0.5 days. This lead-lag relationship can also be seen by inspecting close-zoomed plots of the time series during large anomalies (Fig. 6e). Due to filtering applied to individual instrument data and transport time series, such a short lag is not statistically meaningful.

5 Depth structure of covariability

The hypsometric compensation term ($T_{\text{ext}}$) is mostly depth-independent, but has a vertical profile that scales with the width of the basin as a function of depth. It is nearly uniform
from the surface to about 3500 m, and then decreases gradually to zero at the greatest depths in the basin. If the mid-ocean region had no shear ($T_{\text{int}}=0$) and no flow in the wedge ($T_{\text{wbw}} = 0$), the MO transport would still be non-zero through this applied compensation, in order to balance the northward FC and Ekman transport. In the absence of strong variations in $T_{\text{int}}$, we would expect to see anti-correlation between the MO transports (e.g., the UMO and LNADW) and the independently estimated FC and Ekman transports. In this case, the MO transport fluctuations would then have a depth structure approximately matching the hypsometric profile. Instead, the MO transport-per-unit-depth profiles often show deep maxima below 3500 m in anomaly plots (Fig. 2a).

This deep maximum in transport-per-unit-depth implies that there are considerable changes in the deep shear integrated across the width of the basin, which are reflected in the $T_{\text{int}}$ term. (There is little transport in the $T_{\text{wbw}}$ term below 2000 m.) The $T_{\text{int}}$ term, in turn, is determined by the isopycnal displacements at the eastern and western boundaries, according to a basin-wide thermal wind balance. In the following, we will use isopycnal displacements at the two basin boundaries to investigate the vertical structure of the variability noted above. In the simplest case of a two-layer fluid, a tilted interface marked by the displacement of the interface at the boundaries will have an associated geostrophic shear between the layers. The strength of the shear increases with the tilt of the interface so that if the interface were at a constant depth at the eastern boundary, the shear would be controlled by displacements at the western boundary.

While the stratification at 26° N is more continuous, we use displacements at the two basin boundaries to investigate the magnitude of the shear variability and the role of east and west in producing these shear anomalies. Using the time-mean density gradient profile, given by $\bar{N}^2(z) = -(g/\rho)\partial \bar{\rho}/\partial z$, the contribution of heave to transport-per-unit-depth can be estimated from Eq. (2) as

$$\tilde{T}_{\text{int}}(z) = \frac{1}{f} \int_{z_{\text{ref}}}^{\tilde{z}} \zeta_e \bar{N}_e^2 - \zeta_w \bar{N}_w^2 \, dz' ,$$

(3)
where \( \sim \) distinguishes this portion of \( T_{\text{int}} \) from the more complete calculation in (2). Here, \( \zeta_e(z,t) \) and \( \zeta_w(z,t) \) are the isopycnal displacements at the east and west, respectively. From (3), we might expect some correspondence between isopycnal displacements and transports, though transports are the vertically-integrated transport-per-unit-depth.

Comparing the UMO transport with both eastern and western boundary isopycnal displacement time series, we find strong correlations (Fig. 7a). In the west, displacements between 300 and 1200 m are significantly correlated with the UMO time series, with a peak at 820 m. **Physical expectations** This is consistent with physical expectations, and prior results indicated a role for the displacement of the main thermocline in controlling the UMO transport (Longworth et al., 2011; McCarthy et al., 2012; Duchez et al., 2014). The correlation in the east is of similar absolute amplitude but is spread over a broader depth range (200 to \( \sim \) 1800 m deep), consistent with the findings of Chidichimo et al. (2010) that the eastern boundary density variations were coherent down to 1400 m. **No significant correlations were found between any of the transport components considered here (UMO, FC, LNADW or Ekman) and the isopycnal displacements at the Mid-Atlantic ridge (not shown).**

The FC is also highly correlated with the western boundary thermocline displacement (Fig. 7a). The sign of the correlation has flipped (consistent with the anti-correlation noted between the FC and UMO). This relationship is statistically significant, even though the isotherms covarying with the FC are 150 km away from the FC, east of the Bahamas. As might be expected, there is no statistically significant relationship between the thermocline displacements on the eastern side of the basin and the FC transport. Comparing the time series of western boundary isopycnal displacements at 820 m with the UMO transport (Fig. 8a), we find significant correlation where a 10 m downward displacement of the thermocline corresponds to a 1 Sv increase in the UMO transport (Fig. 8b). Given the one-to-one relationship between the FC and UMO (Fig. 4b), this means that a 10 m thermocline displacement is also associated with a 1 Sv change in the FC.

The correlation between LNADW transport and isopycnal displacements is significant at depth (1500–bottom m–bottom) on the western boundary only (Fig. 7b). The negative correlation can be readily understood in that a depression of deep isopycnals on the western
side of the basin causes larger northward shear below 2000 m. That is to say, a depression of deep isopycnals on the western side of the basin will result in a slowing of the southward LNADW (a northward anomaly) relative to the UNADW layer above it. One remarkable feature of this correlation is that it extends vertically over several thousand meters of water (spanning several moored instruments), so that when water at 3000 m moves upwards, a large segment of the water column above and below is also moving upwards (though with differing magnitudes). In this case, a 42 m downward displacement of the isopycnal at 3140 m results in a 1 Sv reduction in the LNADW transport (Fig. 8d).

Isopycnal displacements in a reduced region (2700–3300 m) at the western boundary are also significantly correlated with the surface Ekman transport (Fig. 7b). Positive (northward) Ekman transport anomalies are associated with upward displacements of the deep isopycnals. This means that when the winds blow along 26°N, the deep ocean responds by heaving upwards or downwards across hundreds of meters, with the end result that these isopycnal displacements at the western boundary change the basin-wide tilt and thus the vertical shear in meridional transports. Just 40 km offshore (25 km further offshore than the western boundary) at the WB3 mooring, isopycnal displacements are still significantly correlated with LNADW transports, albeit more weakly (|r| ≤ 0.5, not shown). Ekman transports are no longer correlated with displacements. At the WB5 mooring, 500 km offshore, there is no relationship between isopycnal displacements and basinwide transport. The strong correlation between isopycnal displacements nearshore and meridional Ekman transport, and the absence of correlation for offshore displacements may indicate that the deep compensation is concentrated at the western boundary, or that other variability in isopycnal displacements masks the signal offshore.

6 Timescales of compensation/covariability

One of the key results presented here is that the UMO and FC transports often compensate each other – i.e. their anomalous variability and magnitudes match, but their signs differ – resulting in greatly reduced impact of their individ-
ual fluctuations on the total MOC variability. However, this compensation is dependent on timescales. At low-frequencies, the compensation is absent (Fig. 4c), and the large interannual variability and trend in the UMO transport has a strong projection onto the interannual variability and trend of the MOC.

To investigate the covariability for different timescales, we evaluate the coherence calculated using a multitaper spectrum following Percival and Walden (1998) (Fig. 9). The FC and UMO are significantly coherent and out-of-phase (i.e., anti-correlated) at periods less than 1 year. For periods longer than about a year they are no longer coherent. For Ekman and LNADW transports, they are coherent at periods shorter than 900 days (except near 120 days) and also (nearly) out-of-phase. By contrast, there is little coherence between the Ekman and FC time series (Fig. 9, grey).

These results at first appear to contradict Kanzow et al. (2010), who noted from the first 3 years of observations (2004–2007) that there was no compensation between the FC and UMO. Using a cross-wavelet transform (Grinsted et al., 2004), we can examine the temporal shifts in covariability between MOC components (Fig. 10). Since 2007 the beginning of 2008, the FC and UMO covary at annual to sub-annual timescales (consistent with the coherence calculation). Prior to 2007–2008 there is no significant covariation between them (Fig. 10a), consistent with the findings of Kanzow et al. (2010). The cross-wavelet transform of LNADW and Ekman shows that the periods of higher co-variability occur in the latter half of the 10 year record (Fig. 10b). There also exists some power at annual timescales and higher frequencies (e.g., during the wind-reversal events in 2005, 2009/10 and 2013).

The compensation between the FC and UMO is non-stationary. A windowed correlation between the FC and UMO prior to 2007 shows no significant correlation, either between the full time series or the high-pass filtered time series (not shown). From Frajka-Williams et al. (2013), the FC and Antilles Current (AC) were correlated between 2009 and 2011. The AC is a narrow, northward boundary current east of the Bahamas. Its transport is measured by direct current meter measurements in the RAPID array, and is included in the UMO transport. The mean transport of the AC is relatively small (3.6 Sv, compared to 31 Sv in the FC), so that the UMO transport is still net southward.
However, since the AC is part of the UMO transport, a correlation between the FC and AC should weaken an anti-correlation between the FC and UMO. The isopycnal displacements associated with UMO and FC variability (Fig. 7) also influence transport in the AC, as long as the AC is geostrophic. The mooring used to estimate isopycnal displacements is at the western edge of the UMO transport, but is east of the core of the northward AC velocities. This means that a downward displacement of isopycnals is associated with an increase in the tilt of the thermocline between Africa and the mooring, but will have an opposing effect on geostrophic transports west of the mooring, in the Antilles Current. Frajka-Williams et al. (2013) identify stronger eddy activity east of the Bahamas during the period of FC and AC correlation, which is consistent with a eddy activity playing a role in the anti-correlation between the FC and UMO on subannual timescales.

7 Trends in isopycnal displacements and MO transports

The MOC at 26° N has been decreasing in strength, as described in Smeed et al. (2014) and this trend continues through early 2014. This low frequency change is mainly associated with uncompensated changes in the UMO transport (variations at timescales longer than 1 year) and to a lesser degree with a weak reduction in the FC transport (Table 1). From the low-pass filtered transport-per-unit depth profiles (Fig. 2b) we noted that changes are present both above and below the thermocline. Here we investigate how the trends in transport are captured by trends in isopycnal displacements.

In the top 1000 m, the isopycnal slope is large, with lighter water in the west. The slope decreases to 0 at about 1000 m, reversing sign between 1000–1500 m, and is typically small below. (Fig. 11a) At the western boundary, isopycnal displacements below 1000 m are moving downwards (trend at 3140 m is \(-6.5 \pm 3.5\) m yr\(^{-1}\), increasing to about \(-13 \pm 0.4\) m yr\(^{-1}\) at 4500 m), while above 500 m they are moving upwards (Fig. 11a11b). At the eastern boundary, trends are near zero except below 4000 m where they are downward. As a result, the east-west slope of isopycnals below 1000 m is decreasing with time. While the largest displacements are seen at depth, stratification is also weaker at depth. From Eq. (3),
we see that the effect of isopycnal displacements on transports is modulated by the back-
ground stratification. Computing instead the trends in isopycnal displacements scaled by
stratification (Fig. 11b11c), we now see that at the western boundary, the effect of isopyc-
nal displacements below the thermocline is nearly constant, with little effect on the eastern
boundary. Scaling by stratification emphasizes the importance of relatively small trends in
displacements in the top 1000 m to transport anomalies.

The trend in $\tilde{T}_{\text{int}}$ from Eq. (3) is shown in Fig. 11c11d, with a persistent reducing trend in
the interior transports associated with heave at the eastern and western boundaries. The
magnitude of the trend increases from 0 at the bottom, since it is integrated upwards from
the bottom. While the thermocline displacement shows little-to-no trend (Fig. 11a11b, the
trend on the western boundary at 830 m is $-0.7 \pm 0.9$ m yr$^{-1}$), the interior transport has
a large negative trend. The large amplitude at the depth of the thermocline results from the
accumulation of persistent negative anomalies between the bottom and the thermocline.
Above 1000 m, the trend in $\tilde{T}_{\text{int}}(z)$ is relatively constant and negative.

An overall southward intensification of $T_{\text{int}}$, if unbalanced by other components, would
result in an intensification of the southward flow across the section and the 10 year period.
To maintain overall mass balance across the section, an opposing trend is required in $T_{\text{ext}}$
(Fig. 11d11e). Trends in the overall mid-ocean transport ($MO(z)$) include those from $\tilde{T}_{\text{int}}$
as well as anomalies in the wedge and compensation, due to stratification changes and
diabatic changes, and both at the boundaries and mid-Atlantic ridge. The overall amplitude
of the trend in MO($z$) is weaker than in $\tilde{T}_{\text{int}}(z)$, but with a greater shear near the surface.
The wedge in particular contributes to the shear in the top 1000 m in MO($z$) relative to $\tilde{T}_{\text{int}}$
(not shown).

The trend in MO($z$) is negative above $\sim 1700$ m and positive below. This amounts to
a rebalancing of the absolute reference level for $T_{\text{int}}$ to account for the changing structure of
the interior ocean shear profile. Summing the $T_{\text{int}}$ and $T_{\text{ext}}$ components results in a north-
ward anomaly below 1700 m (where $T_{\text{ext}}$ exceeds anomalies in $T_{\text{int}}$). The vertical structure
of these trends explain why the LNADW is seen to be consistent with the intensification
of the baroclinic circulation: the LNADW is reducing in intensity (less southward than be-
fore) while the UMO is increasing in southward intensity flow. In addition, the depth of the change in the trend (1700 m) is in the middle of the UNADW layer (1100–3000 m) offering an explanation for why no long term trend is apparent in the UNADW transport.

8 Discussion

Here we have identified significant compensation, dependent on timescale, between components of the MOC: e.g., on sub-annual timescales when the FC is stronger northward in the western boundary, the UMO compensates with stronger southward flow between the Bahamas and Canary islands. While these components are largely independent, they are weakly coupled due to the construction of the MO($z$) transports. The $T_{ext}$ term contributes variability to both the UMO and LNADW transport, and would tend to cause an opposite sign anomaly in both the UMO and LNADW in response to anomalies in the FC and Ekman transports.

However, by construction the $T_{ext}$ term is nearly barotropic, and what limited vertical structure it has arises from the vertical profile of section width at 26° N. This means that $T_{ext}$ distributes compensation for the Ekman or FC anomalies across the full water column, with the strongest compensation in the MO($z$) term occurring in the top 3500 m and reducing to zero at the bottom. Only a fraction of FC anomalies (order 1/5th) would be projected by $T_{ext}$ onto UMO anomalies, and less than half the magnitude of Ekman anomalies would be contained in the LNADW portion of the $T_{ext}$. Instead, the observed transport anomalies in UMO and LNADW are indistinguishable in magnitude to the anomalies in FC and Ekman transports. Furthermore, there is no correlation between the Ekman and UNADW transport, which requires a shear between LNADW and UNADW to remove any projected compensation to Ekman. We can see this baroclinic response in the isopycnal displacements measured at the western boundary.

The compensation between the UMO and FC has the appearance of a time-varying horizontal or gyre circulation, but is limited to sub-annual timescales similar to those of eddies identified in [Frajka-Williams et al. (2013)]. In that paper, on some occasions, when
a large cyclone (anticyclone) impacted the Bahamas (and $T_{wbw}$ transports), the FC would respond by weakening (strengthening). Sea surface height anomalies originating east of the Bahamas coincided with same sign anomalies along the eastern side of the Florida Straits, resulting in transport anomalies of opposite sign to the west and east of the height anomalies. The new result here is that we use the full UMO rather than just the Antilles Current as in the 2013 paper, and the pattern of anti-correlation has persisted since 2007. Because the co-variability of the FC and UMO transports is accompanied by roughly equal magnitude anomalies, there is a reduced projection of either component on the variability on the overall MOC. This is also consistent with the findings of Clément et al. (2014) who used the RAPID data and sea surface height anomalies to show that Rossby waves/eddies with a sub-annual timescale do contribute to dynamic height anomalies at the boundary but do not affect the MOC.

The relationship between surface winds and deep isopycnal displacements is harder to understand, and we presently do not have a dynamical explanation for this behavior. Nevertheless, the observations are quite clear: when there is anomalous southward Ekman transport (resulting from westerly winds), isopycnals at $\sim 3000$ m on the western boundary plunge downwards. From theoretical and numerical model results (Jayne and Marotzke, 2001; Killworth, 2008), it is expected that Ekman transport fluctuations on sub-annual time scales should result in a quasi-instantaneous, and nearly barotropic, compensation in the deep ocean. One might expect that with anomalous southward Ekman transport across the basin, there should be a northward compensation across a broad range of depths, which could also perhaps be spatially distributed. Yeager (2015) showed in a numerical model that Ekman anomalies project strongly onto the barotropic mode promoting wave interactions with deep bathymetry. It is possible that the baroclinic response we observe at 26° N is generated by these barotropic waves interacting with the bathymetry at the western boundary. This is an area for future research – likely requiring numerical modeling to isolate mechanisms and processes.

The observed high-degree of variability on sub-annual timescales of the UMO and LNADW transports may contribute to the apparent absence of meridional coherence be-
tween observations at 26° N and higher latitudes. Elipot et al. (2013) found large coherence on short time scales at mid-latitudes in the North Atlantic, but between 41 and 26° N, transport anomalies were out-of-phase (Elipot et al., 2014; Mielke et al., 2013). The large fluctuations in LNADW transport are remarkably well-captured by ocean bottom pressure from the GRACE satellites (Landerer et al., 2015). However, the spatial footprint of detrended monthly anomalies is centered in the western part of the subtropical North Atlantic, suggesting limited meridional coherence. Using satellite altimetry, Frajka-Williams (2015) found that sea surface height anomalies capture the interannual variability and trend of the UMO transport, with a spatial footprint extending over a larger area.

9 Conclusions

The record of basin-wide MOC transport variability at 26° N in the Atlantic is now ten years long. It continues to deliver new insights into the origins of the changing large-scale circulation at 26° N. With the most recent 18 months of observations, the April 2012 to March 2013 year has the second weakest MOC, behind the 2009/10 year. Unlike the 2009/10 year, the reduction in 2012/13 is associated with an enhanced southward UMO and decreased LNADW, with no contribution from anomalous Ekman transport. There were, however, several wind reversal events in the past latest 18 months, at the end of 2012 and again in March 2013. These events were shorter than the 2009/10 and 2010/11 double dip, though they also resulted in concurrent reductions in the southward LNADW transport.

The main result of this paper has been detailing newly-identified compensations between MOC components (UMO and FC, and LNADW and Ekman). Using the ten-year record, we now find that on shorter timescales (periods shorter than 1 year), much of the variability of the UMO is compensated by the FC transport variability, particularly in the most recent seven years. On similar timescales (periods shorter than 2 years), the wind-driven variability in the top 100 m (surface meridional Ekman transport) is nearly instantaneously balanced by deep flow in the opposite direction. However, rather than being a simple barotropic response
to the winds, the imprint of the winds is baroclinic, with the strongest signature in isopycnal displacements being found just east of the Bahamas at 3000 m depth.

There is a key difference between these two compensating transport pairs. Between the FC and UMO, compensated high frequency transport anomalies results in a horizontal circulation anomaly: that is, northward flow in the FC (in the top 700 m) is accompanied by southward flow in the top 1100 m east of the Bahamas. As a consequence, it is transport anomalies have little influence on the MOC and are unlikely to have a strong heat transport anomaly. By contrast, the southward Ekman anomalies accompanied by northward LNADW anomalies directly projects onto the MOC. During the anomalous periods of exceptionally strong (weak) Ekman transport, the MOC is similarly strong (weak) and we expect the meridional heat transport to vary with the MOC (Johns et al., 2011).

Transport fluctuations on Finally, investigating longer-term variations of the MOC, we can localize the origin of the intensifying trend in the MOC to isopycnal displacements on the western boundary. Observed transport fluctuations on interannual and longer timescales present a different story. From the ten-year record, the mid-ocean transports (rather than FC and Ekman) are primarily responsible for the low frequency variability and trend of the overturning. Furthermore, the trend in transport variability is associated with the persistent deepening of isopycnals below the thermocline at the western boundary. These displacements are greatest in the abyss (130 ± 40 m over 10 years at 4500 m) compared to about 60 ± 30 m at mid-depths around 2000 m, though their impact on transports must be scaled by stratification. While we do not investigate here whether the longer-term isopycnal deepening is associated with watermass changes or wind-forcing, a coincident shift towards warmer and fresher waters below 3000 m (Atkinson et al., 2012) hints at the possibility of larger-scale persistent changes to the Atlantic circulation.

Acknowledgements. Data from the RAPID Climate Change (RAPID)/Meridional overturning circulation and heat flux array (MOCHA), Western Boundary Time Series (WBTS) projects are funded by the Natural Environment Research Council (NERC), National Science Foundation (NSF, OCE1332978) and National Oceanic and Atmospheric Administration (NOAA), the Climate Program Office – Climate Observation Division. Data are freely available from www.rapid.ac.uk
Florida Current transports are funded by the NOAA and are available from www.aoml.noaa.gov/phod/floridacurrent.

Wavelet code provided by A. Grinsted, J. Moore and S. Jevrejeva. Special thanks to the captains, crews and technicians who have been invaluable in the measurement of the MOC at $26^\circ$ N over the past ten years.

Figure 1. (a) Ten-day (colors) and three-month low-pass (black) transport time series of the FC transport (blue), Ekman transport (green), upper mid-ocean transport (magenta) and overturning transport (red) at ten-day resolution. (b) Layer transports for UNADW (1100–3000 m, cyan) and LNADW (3000–5000 m, purple). In both panels, for visualization purposes, the low-pass filter was filtered versions of the time series are shown in black, where transports have been convolved with a 3-Tukey filter 4-month, low-pass Hanning window. Transports are positive northwards. Ten-year mean transports for each component are shown with the dotted lines.
Figure 2. Transport-per-unit-depth anomalies of the mid-ocean transport at 26° N, where the time mean profile over the ten years has been removed. (a) The top panel shows the twice-monthly, deseasonalized variability and (b) the lower panel is further deseasonalized and filtered with the 1.5 year filter. Red (blue) shows transports which are anomalously northward (southward).
Figure 3. Time series of transport anomaly for MOC and components as in Fig. 1, deseasonalized and low-pass filtered with 1.5 year filter.
Figure 4. Transport anomaly time series (left column) for the FC (blue) and UMO (magenta). Zero anomaly is marked with the dashed line. Scatter plots of the same (right column) with correlation coefficients ($r$) noted. In (a, b), the deseasonalized, detrended time series are used. In (c, d), the time series are further deseasonalized and low-pass filtered, but not detrended. The orthogonal regression line is overlaid on the scatter plots. Grey bars highlight periods noted in the text.
Figure 5. As Fig. 4 but for the Ekman and $-\text{LNADW}$ transport anomaly time series.
Figure 6. Ten-day filtered transport anomaly time series of UMO and FC (a, b) and LNADW and Ekman (c, d). The ten-year mean has been removed, but the seasonal cycle and trends are retained. Time ranges have been chosen to correspond to large anomalies in both time series, to visualize possible lags. (e) Lag correlation between ten-day filtered UMO and FC (magenta) and Ekman and LNADW (green). 95% significance is marked by the dashed lines, same color.
Figure 7. Correlation between isopycnal displacements at each depth and transport time series, where time series are deseasonalized and detrended. (a) Correlation between UMO (magenta) and isopycnal displacements at the west (solid) and east (dashed), and between FC (blue) and isopycnal displacements at the west (solid) and east (dashed). Significant correlations are indicated by the thicker line. (b) The same, but for LNADW (purple) and Ekman (green).
Figure 8. Time series of deseasonalized, detrended transports and isopycnal depths. (a) UMO transport (magenta) and the depth of the density surface with mean position at 820 m (highest correlation with UMO) at the west. (c) LNADW transport (purple) and the depth of the density surface with highest correlation (at 3140 m). Scatter plots are shown in (b, d), where the least squares linear regression is overlaid.
Figure 9. Coherence between MOC components: UMO and FC (magenta), LNADW and Ekman (purple green) and FC and Ekman (grey), where time series are the original 10 day filtered (seasonal variations retained). The top panel shows coherence, where significance is delimited by the black horizontal line. The lower panel shows the phase relationship at each period in degrees.
Figure 10. (a) Cross wavelet transform between the FC and UMO shows high power (red) with a fixed phase-relationship since 2007 at periods between 60–400 days. (b) Cross wavelet transform between Ekman and LNADW shows high power primarily at annual periods during the 2009–2010 events, as well as sub-annual from 50–150 days in 2005, 2011, and 2013 (Arrows pointing to the left indicate out-of-phase relationship or anti-correlation, and are only shown when the relationship is significant. Deviations from $180^\circ$ indicate a lag or phase shift.).
Figure 11. Trend in isopycnal displacements and transports. (a) **Mean height difference between isopycnals in the east and west.** (b) Trend in isopycnal displacements at the western and eastern boundaries, where a negative (positive) trend indicates downward (upward) movement of isopycnals. The solid (dashed) line is for displacements at the west (east). (b) (c) Trend in displacements scaled by buoyancy frequency with $N_0 = 1 \times 10^{-3} \text{s}^{-1}$. (c) (d) Trend in $\tilde{T}_{\text{int}}$ from Eq. (2). The red line is the trend in $\text{MO}(z) - T_{\text{ext}}$. (d) (e) Trends in transport-per-unit-depth of mid-ocean (MO($z$)) in magenta, $T_{\text{ext}}$ in blue. All time series were twice-monthly. Confidence intervals on the trends are shaded. The dotted line shows a zero trend.
